

5. Four independent Hispanic or Latin American Δ AUC values, and a wide random-effects interval

Multi-ancestry training. Two scores share one All of Us sample set; the higher PGS ID is the grey point and leaves the random-effects pool. $I^2 = 97$. The fixed-effect interval of all five is narrow. The random-effects interval runs from 0.005 to 0.078 and still excludes 0.

One of the four independent scores is negative and the other three are positive, which is why Q is large.
Random effects is the interval that treats that disagreement as extra uncertainty. Here the extra uncertainty is not enough to include 0.
This cell, and the South Asian cell in plots 1-3, are the type 2 diabetes random-effects results with three or more independent Δ AUC values.
