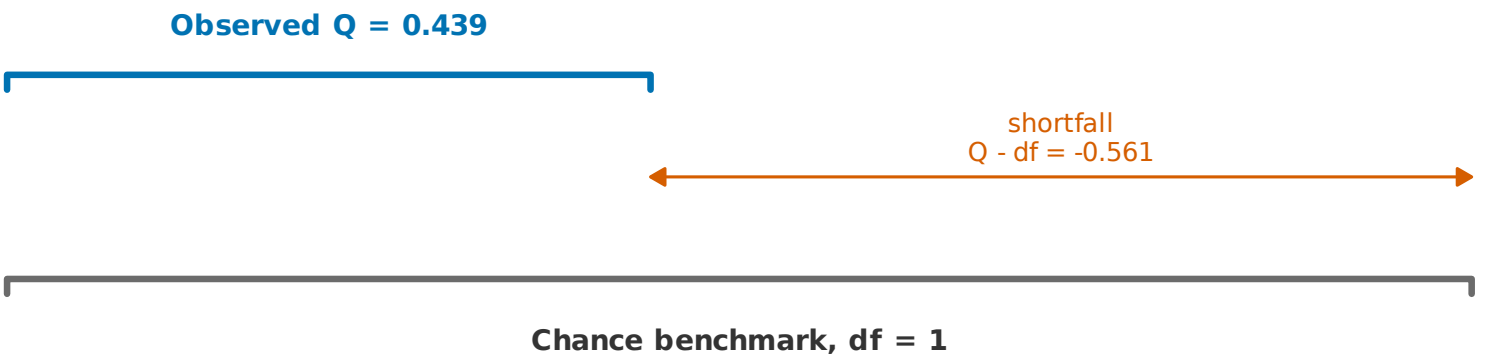
6. I^2 corrects Q by removing the scatter chance is expected to produce

$I^2 = \max(0, (Q - df) / Q) \times 100$.
The numerator drops df, the average Q when sampling error is the only difference.
What remains is a percent of Q. Here that remainder is negative, so I^2 is 0.

PGS001336, the real Q



$(Q - df) / Q = -1.28 \quad \rightarrow \quad I^2 = \max(0, -1.28) \times 100 = 0$

Same correction, if Q had exceeded df

Suppose Q = 4 and df = 1. $I^2 = 3 / 4 \times 100 = 75$

I^2 is the excess slice as a percent of the whole bar.
This bar is not PGS001336. It only shows the same formula.

I^2 does not move the pooled AUC. The pooled AUC stays 0.809.
$I^2 = 0$ means none of Q is extra heterogeneity: the studies agree at least as tightly as their intervals require.
Q is the scatter. I^2 is that scatter after the chi-square benchmark has been removed.
